Pirfenidone induced phototoxic reaction in an elderly man

Sir,

Pirfenidone is an antifibrotic and anti-inflammatory agent used in the treatment of idiopathic pulmonary fibrosis. It reduces fibroblast proliferation, inhibits transforming growth factor-β stimulated collagen production and reduces the production of fibrogenic mediators. Although photosensitivity and rash are reported side effects in clinical trials, we were able to find only a few previously published reports of this adverse effect.¹
Letters to the Editor

A 70-year-old man presented with burning sensation and a rash for 20 days. He had intense erythema with desquamation involving the face, scalp [Figure 1], V area of the chest, shoulder area and upper back [Figure 2] extending to the dorsum of the hands along with involvement of the dorsa of feet up to the ankles. Fissuring was noted over the preauricular area. Characteristic sparing of the periorbital area (patient was using spectacles) and vest covered area was noted. Hair, nail, and mucosae were normal. Skin biopsy was not undertaken.

He had interstitial lung disease and was on treatment with bronchodilators (formetrol, once a day), mucolytics (N-acetylcysteine, 2 teaspoons thrice a day), and pirfenidone for the last 6 months. He had been started on 600 mg/day of pirfenidone 5 months back and the dose was gradually increased to 1200 mg/day. Ten days after escalation of the dose, the patient developed the rash suggesting a dose dependency of the phototoxic reaction. He was managed with oral prednisolone 0.75 mg/kg body weight in a tapering dose along with antihistamines, topical corticosteroids, broad spectrum sunscreens and strict photoprotection.

A diagnosis of drug-induced phototoxic reaction with pirfenidone was made based on clinical examination and history. The differential diagnosis of allergic contact dermatitis, irritant contact dermatitis, and subacute cutaneous lupus erythematosus were excluded on clinical grounds.

Costabel et al. stated that the cutaneous adverse effects of pirfenidone include phototoxic burn-like skin rash on the sun exposed body areas. Skin related photosensitivity reactions were observed in 12.2% and rash was noted in 32.2% of pirfenidone treated patients as reported in the CAPACITY studies. Our patient can be categorized as Grade 3 (erythema with desquamation) which was reported in 0.2% of the drug cohort in the CAPACITY studies. Photosensitivity and rash led to the discontinuation of therapy in approximately 1% of the patient. The mechanism of pirfenidone-induced photosensitivity is likely to be phototoxic and is related to the drug’s ability to absorb ultraviolet A and ultraviolet B. Absorption of ultraviolet light in the skin tissue could result in skin lesions due to generation of reactive oxygen species and lipid peroxidation. Animal studies have shown the use of sunscreens with higher sun protection factor significantly reduce the severity of skin reactions.

The standard approach for preventing and managing skin-related adverse effects include avoiding direct sun exposure, use of broad spectrum sunscreens, physical protection, and avoiding other phototoxic drugs. Costabel et al. have expanded the above guidelines by suggesting behavioral avoidance of indirect sunlight as well as intense artificial light sources, wearing of thick woven cloth and broad brimmed hats and avoiding sun exposure for a few hours following the intake of pirfenidone. The management of the rash includes reduction of the drug dose and discontinuation of the drug in case of persistence of rash for more than 15 days. Slow re-introduction of the drug can be attempted once the symptoms have resolved.
As pirfenidone is also associated with gastrointestinal and neurological side effects, these also need to be carefully monitored. Dose reduction can lessen the gastrointestinal and dermatological side effects.[6]

Declaration of patient consent
The authors certify that they have obtained all appropriate patient consent forms. In the form the patient(s) has/have given his/her/their consent for his/her/their images and other clinical information to be reported in the journal. The patients understand that their names and initials will not be published and due efforts will be made to conceal their identity, but anonymity cannot be guaranteed.

Anal canal adenocarcinoma in a patient with psoriasis treated with etanercept

Sir,

Psoriasis is a chronic inflammatory disease that can affect the skin and joints. The treatment of psoriasis varies depending on disease severity and includes topical and systemic therapies. Among the latter are biological agents that target cellular immunity. The success of biological treatments in patients with psoriasis has generated much enthusiasm within the dermatology community. However, biological treatments may be associated with an increased risk of malignancy because of their immunosuppressive properties. Various case reports have linked them to the development of malignancies such as skin cancers and lymphoma.[1] We report a case of anal canal adenocarcinoma that developed after 10 months of twice weekly etanercept for psoriasis.

A 58-year-old man was diagnosed with psoriasis 3 years ago. The patient underwent a number of systemic treatments and had not taken any other medication except etanercept for about 10 months before the onset of anal symptoms. He had started treatment with etanercept, 25 mg twice weekly subcutaneously about 1 year previously and had tolerated etanercept well.
